

# Exercise No. 7

## Skip List, B-tree

<i>Skip List</i>	
Definition	<p>A skip list is a probabilistic data structure where elements are kept sorted by key.</p> <p>It allows quick search, insertions and deletions of elements with simple algorithms.</p> <p>It is basically a linked list with additional pointers such that intermediate nodes can be <i>skipped</i>.</p> <p>It uses a random number generator to make some decisions.</p>
Skip Levels	<ul style="list-style-type: none"> <li>• Doubly Linked lists <math>S_1..S_h</math>, each starts at <math>-\infty</math> and ends at <math>\infty</math></li> <li>• Level <math>S_1</math> - Doubly linked list containing all the elements in the set <math>S</math></li> <li>• Level <math>S_i</math> is a subset of level <math>S_{i-1}</math></li> <li>• Each element in Level <math>i</math> has the probability <math>1/2</math> to be in level <math>i+1</math>, thus if there are <math>n</math> elements in level <math>S_1</math>, the expected number of elements in level <math>S_i</math> is <math>n/2^{i-1}</math>.</li> <li>• The expected number of levels required is <math>\log_2 n</math>.</li> </ul>
Time Complexity	<ul style="list-style-type: none"> <li>• Search – <math>O(\log n)</math> <b>expected</b></li> <li>• Insert: search and then insert in <math>O(\log n)</math> time – <math>O(\log n)</math> <b>expected</b></li> <li>• Delete search and then delete in <math>O(\log n)</math> time – <math>O(\log n)</math> <b>expected</b></li> </ul>
Memory Complexity	<p><math>O(n)</math> <b>expected</b></p>

### Question 1

Suggest a way to use a skip list to contain numbers in the range  $[1..n]$  ( $n$  is a not constant) and supports the following query:

- Given a pointer to element  $x$ ,  $x.key=i$ , and  $j < i$ , find the element  $y$ , such that  $y.key=j$  in  $O(\log k)$  expected time, where  $k$  is the distance between  $x$  and  $y$ .

### Solution:

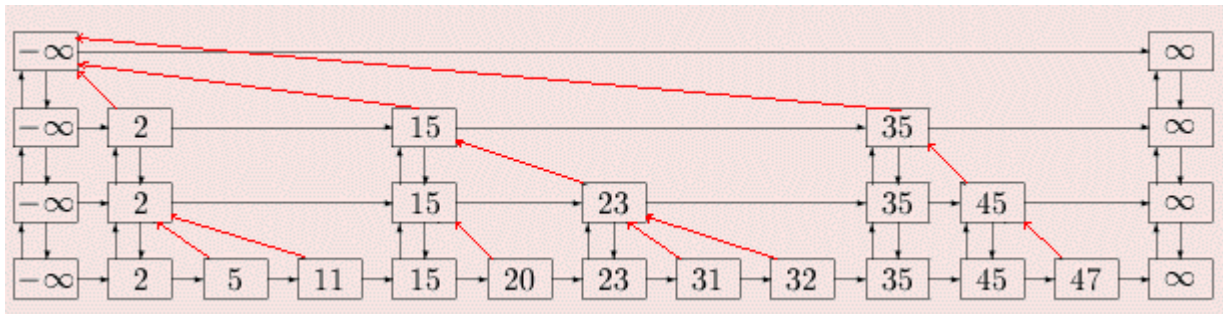

Skip list with the numbers  $[1, 2..n]$  in the lowest level  $S_1$  and  $(-\infty, \infty)$  in the highest level  $S_h$ .

To each element, add a pointer up, to point at the parent in the level above.

Start with the given pointer to element  $x$  in level  $S_1$ , use the 'up' pointers in order to move to a higher level, until the current element's key is  $\leq j$  and it's next element's key is  $> j$ .

From this point start to search the element  $j$  in a the smallest segment in the Skip List, that includes both elements  $x$  and  $y$ .

The additional pointer 'up', marked in red:

**Complexity:** The part of the skip list, where we perform the operations mentioned above is of an approximate size of  $k$ . It can be a bit bigger than  $k$  in case we found a node with  $key < j$ . Therefore, we'll assume that the list is of size  $2k$  in average (just in case). The part of skip list based on the  $2k$  is a tree with height  $O(\log k)$ . So the search on the part of the skip list is like performing the operation on a skip list of size  $O(k)$ . Thus, the search time is  $O(\log k)$  time.

## Question 2

Describe an algorithm  $select(S, k)$  to find the  $k$ -th sized element in a skip list  $S$  with  $n$  elements. You can add a field to each node of  $S$ . The average time of the algorithm should be  $O(\log n)$ .

### Solution:

Each node  $p$  in level  $S_i$  will have an additional field  $dis(p)$  - the number of nodes in level  $S_1$  from  $p$  to the next( $p$ ) in level  $S_i$ . Note that in order to get to the  $k$ -th element, we need to skip  $k$  elements starting from  $-\infty$ .

#### Select( $S, k$ )

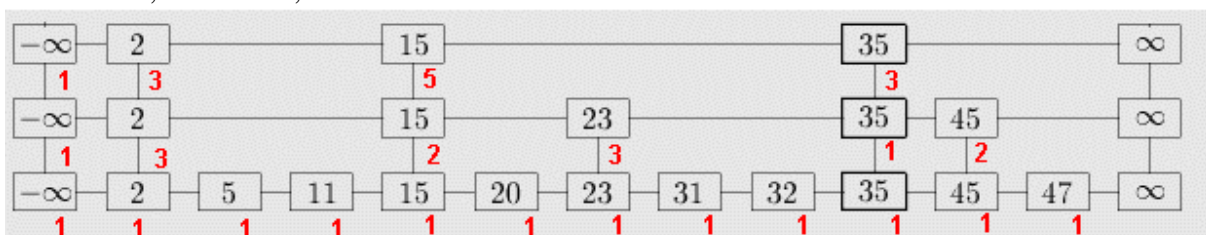

```

p ← leftmost and upmost node of S
pos ← 0
for i ← h (the height of S) downto 1
  while (pos + dis(p) ≤ k)
    pos ← pos + dis(p)
    p ← next(p)
  if (pos = k)
    return p //return the basis of p's tower
  else
    p ← below(p)

```

**Complexity:**  $O(\log n)$ .

**Example:** When searching for the 7-th key (31) the search path is :  $-\infty$ , next to 2, next to 15, down to 15, next to 23, down to 31.

### Question 3

Write an algorithm that builds a skip list  $S$  from the given BST  $T$  with  $n$  elements, such that the worst query time in  $S$  will be  $O(\log n)$ .  $T$  can be unbalanced. The time complexity of the algorithm should be  $O(n)$ .

**Solution:**

```
Build(T, S)  
  S1 ← inorder(T)  
  int i ← 1  
  while (i < log n)  
    for j ← 1 to |Si|  
      if (j mod 2 = 0)  
        Si+1.add(Si[j])  
        Si+1[|Si+1|].setChildPtr(Si[j])  
    i ← i+1
```

Time Complexity: The inorder traversal is  $O(n)$ . The running time of the rest of the algorithm is linear in the number of elements in the skip list, that is  $O(n)$ . The worst query time in such a skip list is  $O(\log n)$ . This question demonstrates how to construct a deterministic skip-list from an ordered set of  $n$  keys in  $O(n)$  time.

## *B-Trees*

<p><b>B-Tree Properties</b></p>	<ol style="list-style-type: none"> <li>1. Each node <math>x</math> has the following fields: <ul style="list-style-type: none"> <li>○ <math>n_x</math> - the number of keys in <math>X</math></li> <li>○ <math>\text{leaf}(X)</math> - true if <math>x</math> is a leaf and false otherwise</li> </ul> </li> <li>2. If <math>X</math> is an inner node with <math>n_x</math> keys <math>(K_1, \dots, K_{n_x})</math> in ascending order, <math>X</math> has <math>n_x+1</math> children <math>(C_1, \dots, C_{n_x+1})</math></li> <li>3. If <math>k_i</math> is the <math>i</math>'th key in <math>X</math>, then all keys of <math>C_i</math> are smaller than <math>k_i</math>, and all keys of <math>C_{i+1}</math> are larger than <math>k_i</math></li> <li>4. All the leaves are in the same level</li> <li>5. <math>t</math> = the minimal rank of a B-Tree Each node except the root, has at least <math>t-1</math> keys and at most <math>2t-1</math> keys</li> </ol>
<p><b>Motivation</b></p>	<p>B-Trees are used when the data size is extremely big and can't be saved in the main memory but in a secondary memory (hard disk ...). Reading from a disk is relatively slow, but B-Trees insure that the number of disk accesses will be relatively small.</p>
<p><b>Theorem</b></p>	<p>If <math>T</math> is a B-Tree with <math>n \geq 1</math> keys then <math>\Rightarrow \text{height}(T) \leq \log_t \left( \frac{n+1}{2} \right)</math></p>
<p><b>Insert(<math>k</math>) (Intuition)</b></p>	<p>Insert in leaf only. Go down from the root to the leaf into which the new key <math>k</math> will be inserted while splitting all full nodes on the path.</p>
<p><b>Delete(<math>k</math>) (Intuition)</b></p>	<p>Go down from the root to a node containing <math>k</math> while making manipulations on the tree to ensure that the current node <math>X</math> (except the root node) on the search path has at least <math>t</math> keys (the ancestor of <math>X</math> may have only <math>t-1</math> keys after the manipulations on <math>X</math>). Thus, when the Delete function gets to a node containing <math>k</math>, the node will have at least <math>t</math> keys.</p> <p><b>Delete (Node <math>X</math>, Key <math>k</math>)</b></p> <ol style="list-style-type: none"> <li>1. If node <math>X</math> has less than <math>t</math> keys (<math>t-1</math> keys) <ol style="list-style-type: none"> <li>a. if node <math>X</math> has a sibling <math>Y</math> with <math>t</math> keys: lend one key from it (key <math>k</math> goes to the father node of <math>X</math> and <math>Y</math>, replaces key <math>k'</math> such that <math>X</math> and <math>Y</math> are its child pointers and the key <math>k'</math> is added to <math>X</math>).</li> <li>b. node <math>X</math> has both siblings with only <math>t-1</math> keys: merge <math>X</math> and one of its siblings <math>Y</math>, while adding the key <math>k</math> from the father node as a median key (<math>X</math> and <math>Y</math> are child pointers of <math>k</math>), into new node <math>W</math>, remove <math>k</math> and pointers to <math>X</math> and <math>Y</math> from the father node, add pointer to the newly created node <math>W</math> to the father node of <math>X</math> and <math>Y</math>.</li> </ol> </li> <li>2. if <math>k</math> is in <math>X</math> and <math>X</math> is an internal node <ol style="list-style-type: none"> <li>a. if the child node <math>Y</math> that precedes <math>k</math> in <math>X</math> has at least <math>t</math> keys: <ul style="list-style-type: none"> <li>-<math>k' = \text{Max}(Y)</math> //find maximal key <math>k'</math> in subtree rooted in <math>Y</math></li> <li>-Delete(<math>Y, k'</math>)</li> <li>-replace <math>k</math> with <math>k'</math> in <math>X</math></li> </ul> </li> <li>b. symmetrically, if the child node <math>Z</math> that follows <math>k</math> in <math>X</math> has at least <math>t</math> keys</li> </ol> </li> </ol>

- k'=Min(Z) //find minimal key k' in subtree rooted in Z
- Delete(Z, k')
- replace k with k' in X
- c. both Y and Z have t-1 keys
  - merge Y, k and Z into one node W
  - delete k from X and pointers to Y and Z and add instead pointer to W
  - Delete(W,k)
- 3. else if k is in X and X is a leaf node
  - a. delete k from X
  - b. return
- 4. else
  - a. find child node  $Y_{i+1}$  of X such that  $key_i(X) < k < key_{i+1}(X)$  // a pointer between  $key_i(X)$  and  $key_{i+1}(X)$  points to  $Y_{i+1}$
  - b. Delete ( $Y_{i+1}, k$ )

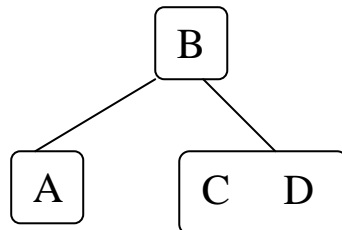

### Question 4

Assume that  $t=2$ . Draw the B-tree that will be created after inserting the following elements (in this order) A,B,C,D,G,H,K,M,R,W,Z.

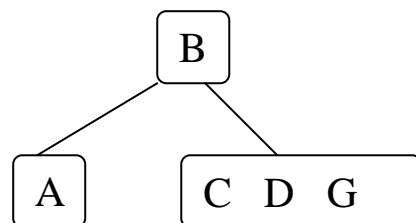

**Solution:**

After a node has 4 elements, it will be split (in here B becomes the root, and the rest of the elements are in its sons).

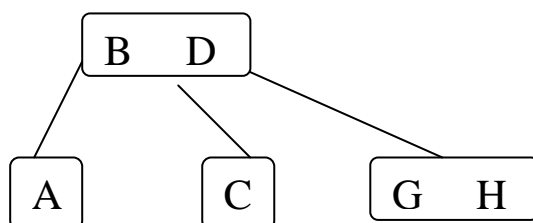

**adding A, B, C, D:**

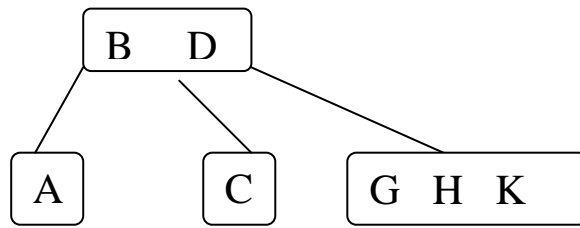

**adding G:**

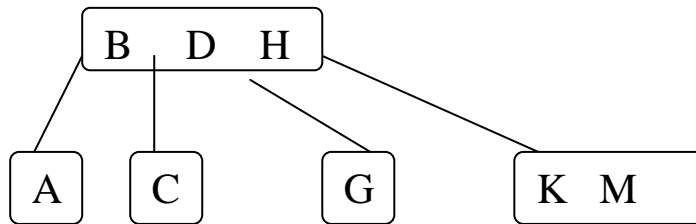

**adding H (C D G H is split. D joins its father):**

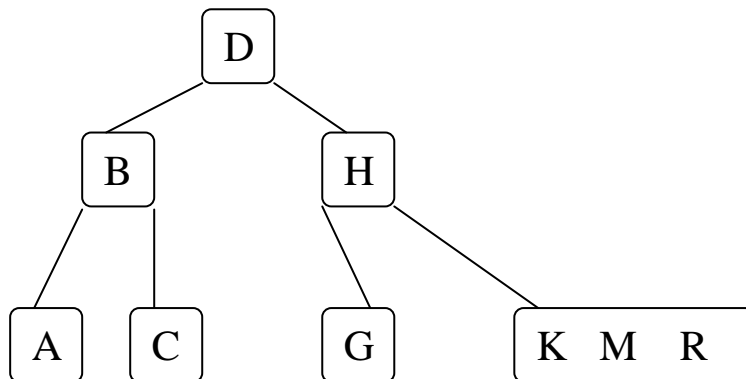

**adding K:**

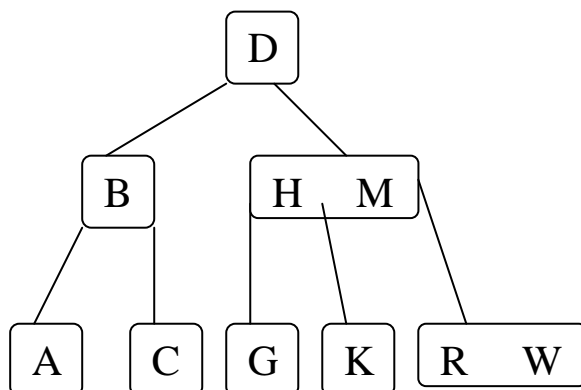

**adding M:**

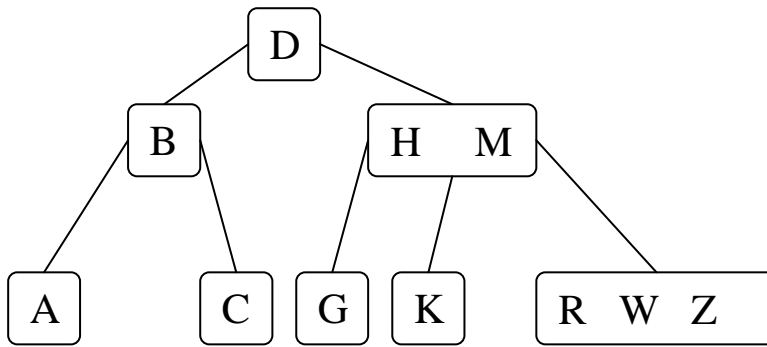

**adding R (BDH is split. The tree is one level higher):**

**adding W (K M R W is split, M joins H):**

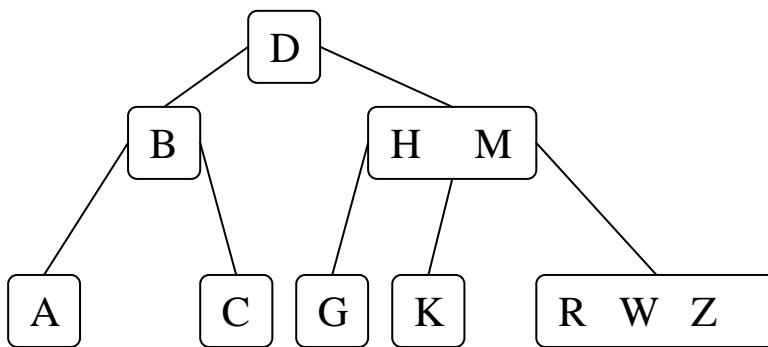

**Adding Z.**

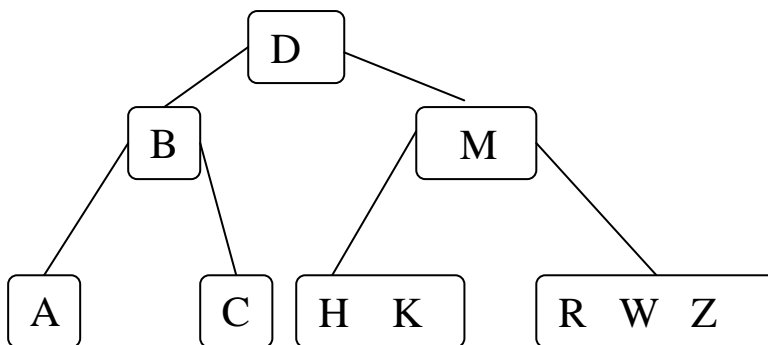

**Question 5**

Assume that  $t=2$ . Draw the tree that will result from deleting the element G, and then M.

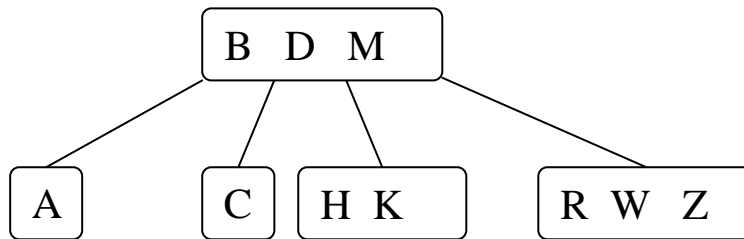

**Solution:**

**Delete G:** root node state is not relevant, node HM has 2 ( $=t$ ) values, node G has  $t-1$  keys, execute 1b: the leaf node will have GHK, delete G from the leaf node)

## Deleting M :

1. execute 1b:

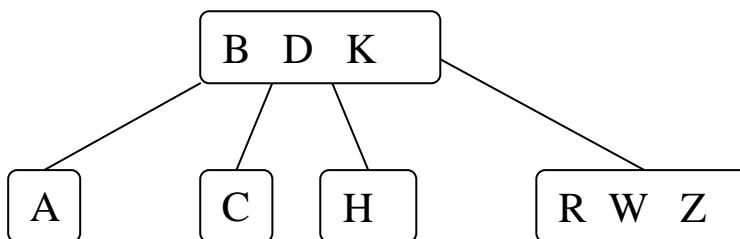

2. execute 2a:

a. find a maximal key in the **left** subtree of M (this is K).

*\*We will always try first to ``take'' a key from the left sibling or a left subtree, and only if it's impossible, ``take'' the key from the right.*

b. delete K from the leaf node HK (then number of keys in the root node is irrelevant and HK has t keys, thus we can delete it right away).

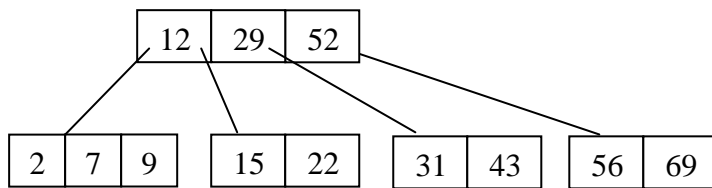

c. K replaces M.

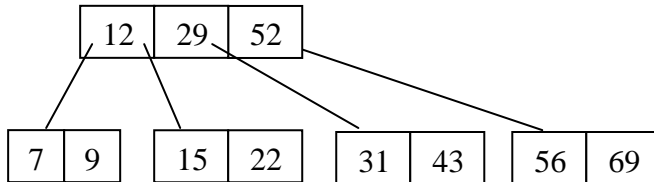

**More examples of deletions:**

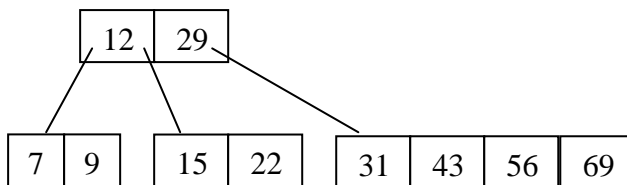

t=3

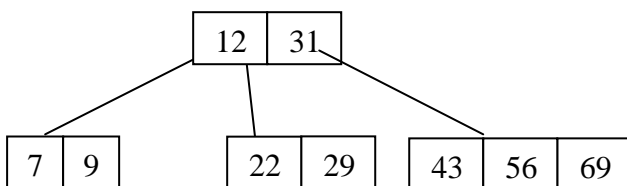

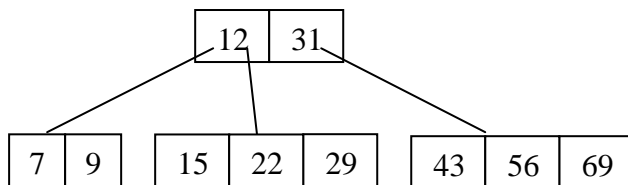

Delete 2:

Delete 52 (2c):

Delete 15 (1a):

## Question 6

Given two B-trees  $T_1$  and  $T_2$ , both with parameter  $t=2$ . Each key in  $T_1$  is smaller than each key in  $T_2$ . Suggest a way to efficiently merge  $T_1$  and  $T_2$  into a single B-tree  $T$  (i.e., in less time than  $O(\log n_1 + \log n_2)$ ).

### Solution:

First find  $h(T_1)$  and  $h(T_2)$  in  $O(h(T_1) + h(T_2))$  time.

(\*) Note that for  $t=2$ , the minimum keys limitation always holds.

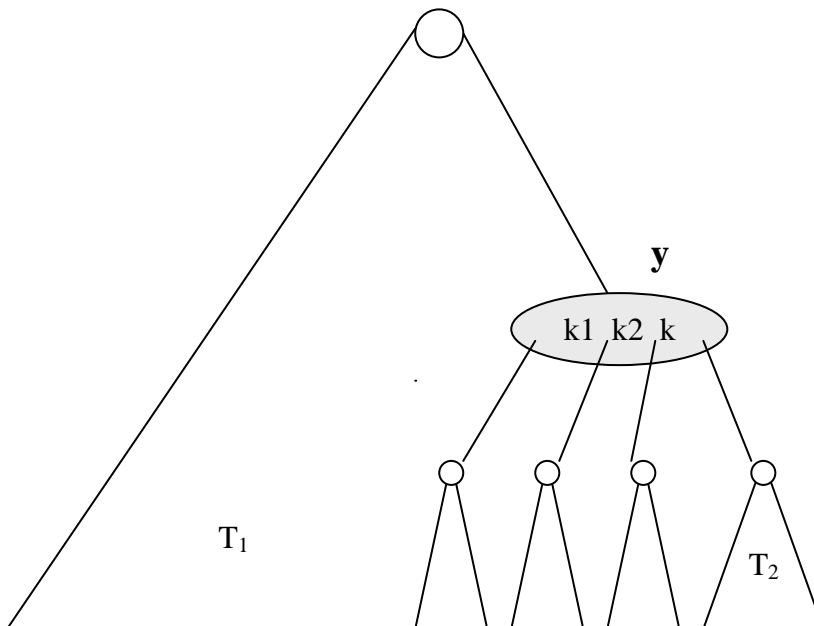

Case a:  $h(T_1) = h(T_2)$ :

- $k \leftarrow \frac{\maxKey(T_1) + \minKey(T_2)}{2}$
- create a new root with the key  $k$  (with null record pointer)
- $T_1$  will be the left sub-tree of  $k$  and  $T_2$  will be the right sub-tree.
- Btree-Delete ( $k$ )

Case b:  $h(T_1) \neq h(T_2)$ :

Without loss of generality assume  $h(T_1) > h(T_2)$ .

- $k \leftarrow \frac{\maxKey(T_1) + \minKey(T_2)}{2}$
- Like in Btree-Insert, go down on the rightmost path in  $T_1$  ( $k$  is larger than all the keys in  $T_1$ ), while splitting all full nodes. Stop at the node  $y$ , such that  $h(y) = h(T_2) + 1$ .  $y$  is not full, i.e., has 2 keys at most.
- Add  $k$  as the largest key in  $y$
- $T_2$  will be the right sub-tree of  $k$  in the node  $y$ .
- Btree-Delete( $k$ )

## Question 7

B-Tree T has  $(10^5+1)$  keys. The maximal number of keys in a node is 17.  
How many disk accesses are required in the worst case while looking for a certain key?

### Solution:

The number of disk accesses = the number of levels in T  
The worst case is when the number of levels is maximal  $\Rightarrow$   
number of nodes is maximal  $\Rightarrow$  number of keys in each node is minimal

The maximum number of keys in a node is 17  $\Rightarrow t = 9 \Rightarrow$  the minimum number of keys in each node other than the root is 8. Each node other than the root has at least 9 children.  
In the worst case the root has only one key, thus 2 children.

Level 0: 1 node  
Level 1: 2 nodes  
Level 2:  $2 \cdot 9$  nodes  
Level 3:  $2 \cdot 9 \cdot 9$  nodes  
...

Level i:  $2 \cdot 9^{i-1}$  nodes

The number of nodes:  $1 + 2(9^0 + 9^1 + \dots + 9^{h-1})$   
The root has one key, every other node has 8 keys, therefore the number of keys is:

$$1 + 8 \cdot 2(9^0 + 9^1 + \dots + 9^{h-1}) = 10^5 + 1$$
$$16(9^h - 1) = 10^5$$
$$9^h = (10^5 + 16) / 16 = 6251$$
$$h = \log_9((10^5 + 16) / 16) \approx 4$$

$h = 4 \Rightarrow$  number of levels is 5 (we started to counting from level 0).  
5 accesses + 1 access for the record page = 6 accesses.

You can use the theorem studied in class:

$h \leq \log_t((n+1)/2)$  and get:  $h \leq \log_9((10^5+16)/16) \approx 4 \Rightarrow h = 4$  (where tree height is the largest depth of a node in T)  $\Rightarrow$  number of levels = 5

## Question 8

What is the value of  $t$  in a system where a pointer size and the size of a key are 2 bytes, and the size of a memory page is 1000 bytes (assume we don't need to keep in the B-Tree node number of keys and the leaf flag).

### Solution:

Memory page = 1 node in the B-Tree.

The structure of a block in a B-tree is (under the stated assumption):

pointer	Key	pointer	...	pointer	key	pointer
---------	-----	---------	-----	---------	-----	---------

When the block is full there are  $2t-1$  keys, and there are  $2t$  pointers.

We would like to use all of the block so we want to find the maximal  $t$  that will fit in a block.

Every key and every pointer cost 2 bytes so:

$$2*(2t-1)+2*2t \leq 1000$$

$$8t \leq 1002$$

$$t \leq 125.25$$

The maximal value for  $t$  is 125.
